INTERNATIONAL FOOD POLICY RESEARCH INSTITUTE

The International Food Policy Research Institute (IFPRI), established in 1975, provides evidence-based policy solutions to sustainably end hunger and malnutrition and reduce poverty. The Institute conducts research, communicates results, optimizes partnerships, and builds capacity to ensure sustainable food production, promote healthy food systems, improve markets and trade, transform agriculture, build resilience, and strengthen institutions and governance. Gender is considered in all of the Institute's work. IFPRI collaborates with partners around the world, including development implementers, public institutions, the private sector, and farmers' organizations, to ensure that local, national, regional, and global food policies are based on evidence.

AUTHORS

ABSTRACT

It is widely acknowledged that unmitigated risks provide a disincentive for otherwise optimal investments in modern farm inputs. Index insurance provides a means for managing risk without the burdens of asymmetric information and high transaction costs that plague traditional indemnity-based crop insurance programs. Yet many index insurance programs that have been piloted around the world have met with rather limited success, so the potential for insurance to foster more intensive agricultural production has yet to be realized. This study assesses both the demand for and the effectiveness of an innovative index insurance product designed to help smallholder farmers in Bangladesh manage risk to crop yields and the increased production costs associated with drought. Villages were randomized into either an insurance treatment or a comparison group, and discounts and rebates were randomly allocated across treatment villages to encourage insurance take-up and to allow for the estimation of the price elasticity of insurance demand. Among those offered insurance, we find insurance demand to be moderately price elastic, with discounts significantly more successful in stimulating demand than rebates. Farmers who are highly risk averse or sensitive to basis risk prefer a rebate to a discount, suggesting that the rebate may partially offset some of the implicit costs associated with insurance contract nonperformance. Having insurance yields both ex ante risk management effects and ex post income effects on agricultural input use. The risk management effects lead to increased expenditures on inputs during the aman rice-growing season, including expenditures for risky inputs such as fertilizers, as well as those for irrigation and pesticides. The income effects lead to increased seed expenditures during the boro rice-growing season, which may signal insured farmers' higher rates of seed replacement, which broadens their access to technological improvements embodied in newer seeds as well as enhancing the genetic purity of cultivated seeds.

1. INTRODUCTION

Agricultural production in developing countries is fraught with various sources of risk. The type and severity of these risks varies by crop or farming system, agroecological conditions, and the policy and institutional settings (Hazell et al. 1986). A seemingly ubiquitous source of agricultural risk is production risk due to weather uncertainty and variability, particularly those associated with deficient rainfall. Various strategies can be taken to mitigate such drought risks, including investments in infrastructure (such as irrigation facilities), technological innovations (such as drought-tolerant cultivars), crop management practices (such as changes to the timing of production activities or reductions in crop durations), and financial instruments (such as credit or insurance). Unfortunately, most of these strategies are often either not available or not feasible for many resource-poor farmers in developing countries. Consequently, not only do droughts often result in lower crop productivity, but the risk of drought provides a disincentive for otherwise optimal investments in new technologies and modern farm inputs (Sandmo 1971; Quiggin 1992). Although these management decisions may reduce income or consumption variability in the short run, they also constrain the farmer's long-run growth potential.

This paper focuses on insurance and assesses the degree to which insurance markets can be developed for resource-poor farmers in low-income settings and incentivize optimal agricultural investments. Conventional indemnity-based crop insurance—which insures farmers against assessed crop losses—is problematic due to asymmetric information (resulting in moral hazard and adverse selection) and high transaction costs (Hazell 1992; Morduch 2006; Barnett et al. 2008). Index insurance, on the other hand, provides insurance coverage on the basis of observed indexes, such as weather conditions measured at a local weather station or average yields in a given area, rather than directly assessed individual yield or profit losses (Giné et al. 2008; Karlan and Morduch 2009; Morduch 2006). Because index-based insurance does not require verification or assessment of losses at the farm level, it minimizes asymmetric information and drastically reduces the delays and costs associated with conventional crop insurance, including both administrative and reinsurance costs (Barnett and Mahul 2007). For these reasons, many development practitioners and policy makers are cautiously optimistic about the potential for index insurance to stimulate agricultural investment and productivity (Alderman and Haque 2007; Hazell et al. 2010).

Because payouts are made on the performance of an index, however, they are not always commensurate with the losses that a farmer has experienced, and this leads to basis risk—the risk that the farmer might experience a loss and receive no insurance payout because it is not a loss that is reflected in the index (Clarke 2016). As a result of this and other factors that constrain demand (such as liquidity constraints, limited knowledge of the product, and lack of trust in insurance providers; see Cole et al. 2013; Giné et al. 2008; Giné and Yang 2009; Hill et al. 2016), many of the index insurance programs that have been piloted to date have met with limited success (for example, see the review in Binswanger-Mkhize 2012). When insurance is adopted at reasonable scale, however, much of the emerging evidence suggests it is successful in encouraging agricultural investment (Karlan et al. 2014; Elabed and Carter 2015; Mobarak and Rosenzweig 2013; Berhane et al. 2014).

This study assesses both the demand for and the effectiveness of an innovative index insurance product designed to help smallholder farmers in Bangladesh manage risk to crop yields and the increased production costs associated with drought. Although most observers might not think of Bangladesh as being particularly prone to droughts, droughts are observed to cause significant damage to an estimated 2.32 million hectares of the transplanted aman (monsoon-season rice) crop each year, with serious nationwide droughts occurring roughly once every five years (Ramamasy and Baas 2007). The widespread increase in the availability and use of irrigation in recent years has allowed Bangladeshi farmers to mitigate the impact of drought on production, but the use of irrigation to do so is costly, such that rainfall deficiencies can ultimately result in significant increases in the costs of production, in addition to any residual impacts on yields. These risks associated with production costs and farm profits may be masked in any index that is solely focused on yields, despite the fact that profit risks may be the most salient to

farmers making decisions about costly and risky inputs. To address these risks, the index insurance product evaluated in the present study was designed to provide payouts primarily on the number of consecutive dry days observed during the monsoon season. But because there is an imperfect correlation between weather conditions and crop production, such an index insurance product necessarily implies nontrivial basis risk. Because area yield indexes are agnostic regarding the cause of the yield losses, many have advocated the use of such indexes where possible in order to reduce basis risk. Indeed, average area yield is the index used in most index insurance products sold in Asia (Clarke 2016; Cai 2016). The product evaluated in the present study therefore incorporated an area yield index that could potentially be triggered if the dry-day index were not triggered. To our knowledge, this is the first study to evaluate a product designed to cover both yields and costs to production.

The randomized controlled trial (RCT) described here was designed to evaluate a local nongovernmental organization's (NGO's) index insurance pilot program in Bogra district in northwestern Bangladesh during the 2013 aman season. Although not directly tied to rice production, the insurance product was intended to cover production risks on a 10-decimal (0.1-acre) plot of land during the aman season. Discounts and rebates were randomly allocated to villages to encourage insurance take-up, to allow the price elasticity of demand to be calculated, and to evaluate the trade-off between providing discounts and rebates. A priori, one might expect that discounts would be preferred to rebates, given that they help address liquidity constraints at the time of insurance purchase. Additionally, evidence from various studies in several developing countries suggests that individuals value the present more than the future and would therefore prefer the immediate benefit of a discount to the delayed benefit of a rebate. Along similar lines, individuals may prefer the discount because there is more certainty associated with a discount now, whereas the promise of a rebate in the future entails some uncertainty. Interestingly, however, despite the uncertainty, this promise of a future payment may be alluring for some farmers. In the context of insurance, rebates provide a certain payout in the future regardless of whether the insurance pays out, and this arrangement has been shown to be preferred in Burkina Faso (Serfilippi et al. 2016).

We find insurance demand to be moderately price elastic. The incentives offered were quite high, and as a result, a large proportion of households purchased at least one unit of insurance. Discounts were significantly more successful in stimulating demand than rebates, which entail a sizable lag between when the purchase is made and when the benefits of the incentive are realized. The price elasticity implied by the results suggests that there would need to be a 14 percent discount or a 34 percent rebate relative to the actuarially fair price of insurance in order to stimulate purchases of a single unit of insurance. It is possible that the discounts required to sustain demand would fall over time as farmers come to know and value the product, but the high level of discount required suggests that an unsubsidized private crop insurance market could not persist in Bangladesh. Despite the preference for discounts in aggregate, we find some significant heterogeneity in demand responses to a rebate, suggesting that some individuals, particularly those who are especially risk averse or sensitive to basis risk, may implicitly view the rebate as a commitment savings mechanism that can offset the costs of insurance contract nonperformance, especially if they experience an on-farm loss yet are not indemnified by the insurance.

Consistent with theory, insurance resulted in increased investment in risk-increasing agricultural inputs during the aman rice-growing season. The coverage of the cost of production risk in the insurance contract also increased use of irrigation to mitigate the yield impact of the long dry spell that was recorded in the 2013 aman season. Somewhat surprisingly, an increase in pesticide use was also recorded, suggesting that perhaps index insurance is not plagued by the same problems of moral hazard as indemnity insurance. The dry spell in the 2013 aman season was long enough to trigger an insurance payment, which was disbursed prior to land preparation in the subsequent boro rice-growing season. The disbursement of insurance payments provided farmers with a liquidity injection that led to increased investments in risk-increasing modern agricultural inputs related to boro production. Although there was no significant effect on rice production or productivity during the aman season, the increased investment in modern inputs during the boro season led to a roughly 8 percent increase in boro production.

The remainder of this paper is organized as follows. Section 2 provides a brief literature review on the determinants of insurance demand and the impacts of index-based insurance—particularly on investments in modern agricultural inputs. Section 3 describes the experimental context, the insurance product, and experimental design. Section 4 presents the empirical results on determinants of insurance demand, and Section 5 presents findings on the impact of insurance on agricultural input use. Section 6 offers some concluding thoughts and reflections, and discusses the policy implications of the findings.

2. REVIEW OF THE LITERATURE ON THE IMPACTS OF INSURANCE AND DETERMINANTS OF INSURANCE DEMAND

Insurance is expected to have both ex post and ex ante impacts on farm households. The ex post benefit of insurance arises as households' trade income in good states of the world for income in bad states of the world. When insurance is actuarially fairly priced, this structure will result in welfare gains for any risk-averse individual. The ex ante impacts are more nuanced and are associated with the expected effects of risk transferal on farmers' production decisions. Dating back to Sandmo (1971) there has been at least a theoretical understanding that risks act as an impediment to what would otherwise be profit-maximizing investments. While Sandmo (1971) was primarily concerned with producer behavior under output price risk, Quiggin (1992) demonstrated a similar result with respect to production risk which in many ways, is the most salient source of risk faced by smallholder farmers in developing countries. Quiggin (1992) showed that input use responses to risk depend crucially on the risk preferences of the producer and the risk profile of the input. Unsurprisingly, risk-neutral producers behave as predicted by expected utility theory. Under production risk, risk-averse producers increase their demand for risk-reducing inputs (such as pesticides) and reduce their demand for risk-increasing inputs (such as fertilizers) relative to risk-neutral producers. This indicates that, assuming the inputs are not costless, insurance increases overall exposure to high production outcomes for risk-averse producers. The theoretical results are ambiguous for mildly risk-increasing inputs and depend upon the marginal product of the input and its subsequent impact on the countervailing risk and moral-hazard effects.

Despite frequently strong theoretical arguments for insurance, attempts to provide formal, indemnity-based crop insurance in many developing countries have struggled, arguably due to poor contract performance, asymmetric information, high transaction costs, and high exposure to covariate risks (Barnett et al. 2008; Hazell 1992; Carter et al. 2016; Binswanger-Mkhize 2012). To circumvent some of these impediments, policy makers and development practitioners have turned to index-based insurance programs, which base insurance payments on the performance of some transparent, easy-to-measure index relative to some benchmark.

Index-based insurance products have several advantages over traditional crop insurance (for example, Miranda 1991). First, payments are based on index triggers that are typically easy to observe and measure, making the index more transparent to the insured, minimizing asymmetric information between the insured and insurer, and reducing the probability of adverse selection and moral hazard (Clarke et al. 2015). These qualities allow for payments to be calculated easily and distributed in a timely manner. Additionally, because insurance payments are based on an index rather than loss adjustments calculated for each farm that is insured, operating and administrative costs may be significantly lower than those of other types of agricultural insurance (Barnett et al. 2008). Along the same lines, contracts can be standardized and need not be tailored to the individual needs of different policyholders (Skees 2008). Finally, because the index triggers are independently measured and easily verifiable, local context knowledge becomes relatively unimportant, so it is easier for reinsurers to understand risks (Alderman and Haque 2007). Within much of the development practitioner and donor community, index insurance is seen as having the potential to provide vulnerable farming households with an important and valuable type of safety net that can stimulate agricultural growth and development (Hazell et al. 2010).

Despite these benefits, however, index-based insurance is hardly a panacea. Farmers receive compensation only when the level of the index relative to some threshold triggers payouts. Since most indexes are tied to observable weather outcomes that are only imperfectly correlated with on-farm losses (for example, Rosenzweig and Binswanger 1993), there is a nontrivial probability that farmers will not be compensated even when they realize significant on-farm losses. Perils unrelated to the index such as soil conditions, pest and disease infestations, and farmer illness also affect yields. The residual risk that a farmer may incur a large loss and still not receive any payment from the insurance contract (for example, if weather conditions on the farm differ from those at the weather station at which the index components are

measured) is referred to as *basis risk*, and has been shown to pose a major deterrent to index insurance uptake (Clarke 2011; de Nicola 2015; Hill et al. 2013; Mobarak and Rosenzweig 2012).¹ Indeed, across various countries and contexts, uptake of index insurance has been low, even when offered at better-than-competitive rates.²

Among the many reasons cited for low take-up of index insurance products are those related to liquidity constraints, basis risk, trust in the insurance provider, and temporal disparities between when premiums are due and when potential payouts are received. An important feature of insurance contracts, particularly as they pertain to resource-poor farmers, is that they entail a current cash outflow with the potential for an uncertain payout in the future. This can be a significant deterrent to demand for insurance among individuals who are liquidity constrained. Trust in the insurance provider also becomes important, and those same individuals are likely to demand insurance only if they have a relatively high confidence that the insurance claims will actually be honored if due (for example, Karlan et al. 2014).

As a normal good, both the individual demand for an insurance policy and the cumulative sales of insurance policies should be declining in the price of the insurance policy. Indeed, this is one of the few empirical regularities, though admittedly with varying degrees of consistency across contexts. Cole et al. (2013) found insurance demand in the Indian states of Andhra Pradesh and Gujarat to be highly price elastic, with a 10 percent reduction in the price of insurance associated with a 10–12 percent increase in insurance take-up. Numerous other studies have also emphasized the role of monetary encouragements in increasing insurance demand. In their study in Ethiopia, McIntosh et al. (2013) found that 25 percent of those randomly allocated to an insurance treatment group ultimately took up insurance, but the evidence suggests that demand might have been nonexistent in the absence of a sizable subsidy. Karlan et al. (2014) found that 40–50 percent of Ghanaian farmers purchased insurance at actuarially fair prices, but take-up rates dropped to 10–20 percent when charged double the actuarially fair price. Mobarak and Rosenzweig (2012) found the price elasticity of insurance demand to be -0.44 and Hill et al. (2016) estimated the price elasticity as -0.58.

Beyond price, other factors affect demand for insurance. Demand for indemnity insurance is increasing in the degree of risk aversion, increasing in the expected payout, and increasing in the size of the insured risk (that is, the magnitude of the potential losses; for example, de Nicola 2015; Clarke 2016). In the presence of basis risk, insurance demand is initially increasing in risk aversion before decreasing such that, for very risk-averse farmers, purchasing insurance actually makes them *worse* off (Clarke 2016). This phenomenon captures decision makers' tradeoff of the benefits of the increase in expected wealth when the index insurance contract performs (that is, under scenarios in which on-farm conditions match those at the weather station at which the index is measured) against the cost of basis risk when the contract does not perform (particularly, states in which the farmer experiences on-farm losses yet the index is not triggered).

Empirical evidence further substantiates these theoretical claims. Hill et al. (2016) found that demand for index insurance is inverse U-shaped in risk aversion, with price sensitivity decreasing at higher levels of basis risk. Mobarak and Rosenzweig (2012) found that for every 1-kilometer increase in the perceived distance of a farmer's land from the weather station, the demand for index-based insurance dropped by more than 6 percent. Hill et al. (2016) found that doubling the distance to the reference weather station decreased demand by 18 percent. Similarly, using willingness-to-pay estimates in Ethiopia, Hill et al. (2013) found an inverse relationship between basis risk and insurance demand, especially at high prices. Based on a discrete choice experiment in eastern India, Ward and Makhija (2016) found that, for every 1 percent increase in basis risk, farmers would need to be compensated with a 3–4 percent reduction in the cost of insurance.

¹ Though basis risk is commonly conceptualized as the mismatch between weather conditions on farmers' fields and those at the weather station or other site at which the weather variables constructing the index are measured, it more broadly refers to any genesis of insurance contract nonperformance, which in this case refers to any farm losses not compensated for, including—but not limited to—those arising due to the aforementioned mismatch in weather conditions.

² A prominent counterexample to this widely observed phenomenon is the study by Karlan et al. (2014) in Ghana. Even at the actuarially fair price, 40 to 50 percent of the farmers in their sample demanded insurance, and on average they purchased coverage for more than 60 percent of their cultivated area.

Understanding the determinants of insurance demand is important for the development of a viable insurance market. But if insurance does not induce investments in higher-risk, higher-return activities, then it essentially yields little value and may not merit public support using scarce resources. Fortunately, in cases in which sufficient uptake has occurred, impacts of index insurance have largely been positive (Carter et al. 2014). Evidence from multiple empirical studies supports the underlying hypotheses that insurance increases household consumption and incentivizes farmers to take greater risks, spend more on their farms, and realize the benefits of higher yields or output. Using data from an RCT on an innovative microinsurance product in Kenya, Janzen and Carter (2013) found that insurance positively affected pastoral farm households following a shock: asset-rich households were less likely to engage in distress sales of livestock to smooth consumption, and asset-poor households were less likely to destabilize consumption by reducing meals. Hill and Viceisza (2012) used games to hypothetically answer the question of whether insurance encourages farmers to take great, yet profitable, input use risks and found a positive impact of insurance on fertilizer purchases. Karlan et al. (2014) found that insurance led Ghanaian farmers to increase agricultural expenditures on their farms along both the extensive and intensive margins. In particular, they found that insured farmers cultivated nearly an acre more land and spent nearly 14 percent more on land preparation (increasing along the extensive margin) while simultaneously increasing expenditures on modern inputs (mostly fertilizers) by nearly 24 percent (increasing along the intensive margin). In Andhra Pradesh, India, Cole et al. (2013) found that insurance caused farmers to invest in higher-return—albeit rainfall-sensitive—cash crops. In Tamil Nadu, India, Mobarak and Rosenzweig (2012) found that farmers who were insured shifted to high-yielding rice varieties over lower-yielding, drought-tolerant ones. They also found that formal insurance was an enabling factor in households' risk-taking decisions. In the context of a field experiment in Senegal and Burkina Faso, farmers who purchased more weather index insurance had higher average yields and were better able to manage food insecurity and shocks (Delavallade et al. 2015). Berhane et al. (2014) found that fertilizer use was 13 percentage points higher among insured farmers in Ethiopia.

3. STUDY CONTEXT AND EXPERIMENTAL DESIGN

Context and Overall Study Design

This study took place in the Bogra district of Rajshahi division in northwestern Bangladesh. Bogra is largely rural, and livelihoods there are heavily dependent upon agriculture, with rice double-cropping being the predominant cropping system. While much of Bogra is characterized by alluvial soils fertilized by siltation from floodwaters, much of it is simultaneously drought prone: farmers in Bogra identified drought and crop diseases as the major sources of crop loss during aman season (Clarke et al. 2015). During the annual monsoon season, in which Bangladesh receives roughly 80 percent of its annual rainfall, there are three distinct types of droughts. Early-season droughts arise due to the delayed onset of the annual monsoon and can affect the timing of activities such as transplanting, which in turn affects both the area cultivated and yields. Midseason droughts typically arise as intermittent, prolonged dry spells and, depending on their timing, can reduce crop productivity. Finally, late-season droughts arise due to early monsoon cessation and are particularly damaging for rice production because they tend to coincide with the flowering and grain-filling stages in the crop growth cycle.

The study was implemented with the cooperation of a local NGO, Gram Unnayan Karma (GUK), that provides a range of services to households in Bogra, including microfinance, nonformal primary education, primary healthcare, and women's empowerment activities. GUK was established in 1989 and operates primarily through village-level groups consisting of female "members" who voluntarily register to participate in and benefit from GUK activities. The study was initiated with a baseline survey in the spring of 2013 and culminated with a follow-up survey a little more than 12 months later (see Table 3.1).

Three *upazilas* (subdistricts) within Bogra were selected on the basis of proximity to the district meteorological station operated by the Bangladesh Meteorological Department (Figure 3.1). Within each of the three selected *upazilas*, 40 villages were randomly selected for inclusion in the study. From within each of these 120 villages, a sample of GUK members (averaging between 15 and 20 members per village) was randomly selected to participate in the study. The baseline survey proceeded in May 2013 among the total sample of 2,300 households from these 120 villages.³ GUK marketed the index insurance product (described in greater detail later in this section, under "The Insurance Product") in half of the sample villages (the randomly-assigned treatment villages) from late May until late June. The coverage period for the insurance policy ran from mid-July to mid-October, as described below. Payouts were made in November 2013 and follow-up surveys were conducted from June to July 2014. All told, attrition proved to be a very minor concern, with virtually all (97 percent) of the households interviewed during the baseline survey also interviewed during the follow-up survey.⁴

³ While the initial sample consisted of 2,300 agricultural households, in the ensuing analysis it is restricted to include only those that cultivated rice, the predominant crop in Bangladesh.

⁴ Although there was very little attrition between baseline and follow-up, the sample sizes that emerge in Tables 3.2, 4.1, 5.1 and 5.2. are smaller than the original sample due to missing observations on key data.

Note: Agricultural timeline based on focus group discussions carried out prior to the initiation of the study and reflecting consensus opinions of focus group members. Due to various factors, including weather conditions, soil variability, seed varieties, labor supply constraints, and so on, the timing of agricultural activities and crop growth cycles varies.

Figure 3.1 Location of sample *upazilas* in Bogra district, Rajshahi division, Bangladesh

Source: Authors.

Table 3.2 presents average characteristics of households in the sample by treatment category. By and large, there are few systematic differences between households in treatment villages and those in comparison villages, which bodes well for subsequent efforts to econometrically identify treatment effects. The overall sample presents the following characteristics on average. Roughly 96 percent of the households were headed by males, who, on average, were about 43 years of age. Among these household heads, the number of years of schooling completed averaged about 3.5. Households owned and cultivated 5.4 different plots, totaling roughly 94.2 decimals (0.94 acres) of land for all crops in the 12-month recall period prior to the baseline survey in 2013, including 52 decimals cultivated under aman rice and 63 cultivated under boro rice. A little more than a quarter (30 percent) of the sample owned a savings account with a bank, though on average fewer than 20 percent of households were members of informal savings groups.⁵ Nearly all households (91 percent) had taken a loan in the 12-month recall period prior to the baseline survey. All of these characteristics indicate familiarity with financial products and formal institutions, suggesting some basic capacity to understand the insurance product.

⁵Here, we acknowledge that there is a slight imbalance between households in treatment and comparison villages. In our treatment villages, roughly 17 percent of households were members of informal savings groups, compared with about 21 percent of households in the comparison group.

Table 3.2 Characteristics of households in randomly allocated treatment and comparison villages

| Household characteristics | Sample | Comparison | Treatment | Difference |
|---|----------------------|----------------------|----------------------|---------------------|
| Gender of household head (male = 1) | 0.96 (0.00) | 0.95 (0.01) | 0.97 (0.01) | -0.02 [0.04] |
| Age of household head | 42.74 (0.26) | 42.55 (0.38) | 42.92 (0.38) | -0.36 [0.49] |
| Household size (persons) | 4.33 (0.03) | 4.26 (0.04) | 4.39 (0.04) | -0.13 [0.04] |
| Education (highest class completed) of household head | 3.52 (0.09) | 3.37 (0.13) | 3.67 (0.13) | -0.29 [0.10] |
| Total land owned and cultivated (decimal) | 94.13 (1.98) | 94.66 (2.71) | 93.62 (2.67) | 1.04 [0.79] |
| Number of years household has been a member of GUK | 3.82 (0.07) | 4.09 (0.10) | 3.56 (0.09) | 0.53 [0.00] |
| Household has a savings account with a formal bank (=1) | 0.29 (0.01) | 0.30 (0.01) | 0.28 (0.01) | 0.02 [0.33] |
| Household cash savings is adequate | 0.31 (0.01) | 0.26 (0.02) | 0.35 (0.02) | -0.09 [0.00] |
| Household is a member of an informal savings group (=1) | 0.19 (0.01) | 0.21 (0.01) | 0.17 (0.01) | 0.04 [0.03] |
| Household asset index (PCA) | 0.06 (0.02) | 0.01 (0.03) | 0.11 (0.03) | -0.10 [0.03] |

Note: Figures in parentheses are standard errors of sample means. Figures in brackets are *p*-values from parametric tests of differences in sample means. BDT = Bangladeshi takas; GUK = Gram Unnayan Karma; PCA = principal components analysis.

Households in our sample had been GUK members for about 4 years, though those who resided in villages randomly allocated to the insurance treatment group had a slightly shorter legacy than those residing in villages randomly allocated to the comparison group (3.6 years versus 4.1 years). The fact that households in the treatment villages had typically maintained a relationship with the organization providing insurance is important. The level of trust in our sample was quite high (5.2 on a scale of 0 to 7, where 7 is someone who is completely trusting).⁶ Trust in and familiarity with the insurance provider has been shown to be an important determinant of insurance demand and can have implications for uptake (Karlan et al. 2014). The saliency of this characteristic may be magnified for households that are risk averse. Households in the sample showed an average level of partial risk aversion of 3.7, which is classified as “severe” according to Binswanger (1980).

When considering outcome variables of interest, we note there are few systematic differences in households in treatment and comparison villages along most agricultural dimensions at baseline. Total output and expenditures on seed, fertilizers, and pesticides during the aman 2012 season are statistically indistinguishable between treatment and comparison villages, as are all agricultural outcomes during boro 2012/2013. Households in the treatment villages did, however, spend less on hired labor and more on irrigation during aman production in 2012.

The Insurance Product

The insurance policy covered the aman season (July 15–October 14, inclusive), a period characterized by large amounts of rainfall on average, but also with significant variability (Figure 3.2). Although the aman rice crop is largely rainfed, we also note that there is widespread evidence of functioning irrigation markets during this season as well, with groundwater irrigation serving to supplement deficient rainfall. The insurance product protected households against a long period of successive “dry days” during the aman season and against low average area yields as a result of overall rainfall deficiency, pests, crop diseases, or flood.⁷

⁶ The measure of trust reported here is derived from a simple, equally weighted index based on responses to a series of scale-response questions about respondents’ level of trust in various actors, and was not specific to GUK.

⁷ A “dry day” is any day in which the cumulative rainfall is less than 2 mm.

Figure 3.2 Historical distribution of rainfall by month, Bogra district, Bangladesh

Source: Authors, based on rainfall data from the Bangladesh Meteorological Department weather station in Bogra district, 1980–2010.

Note: Boxes denote the 25th and 75th percentiles of the historical data, and whiskers (extensions) denote 1.5 times the interquartile range.

According to the policy specifications, the insured would receive a payout if a long period of successive dry days was recorded at the local weather station *or* if the average area yield in the *upazila* was very low. Table 3.3 describes these events and how they relate to policy triggers and corresponding payouts. The dry-days triggers were established based on 30 years' worth of historical rainfall data from the Bangladesh Meteorological Department. If the longest dry spell that occurred lasted at least 14 days, the policy would pay out BDT 600.⁸ On average, this type of dry spell occurs roughly once every decade. If the longest dry spell that occurred lasted 12 or 13 days, the policyholder would receive a payment of BDT 300. This type of dry spell occurs roughly once every five years, on average.⁹ Actual rainfall measurements were recorded at the *upazila* agricultural extension offices in each of the three *upazilas*, allowing for potential heterogeneity in rainfall realizations—and thus the performance of the index insurance product—over space. If the dry-days triggers were not met, the insurance could still be triggered

⁸ BDT = Bangladeshi takas. At the time of the intervention, the exchange rate was approximately BDT 76 per US\$1.

⁹ The return periods for these triggers are based on the assumption that the annual maximum dry spell is distributed according to a generalized extreme value distribution. The location, shape, and scale parameters of this distribution were estimated using maximum likelihood and then used to estimate the levels (that is, dry spell lengths) associated with the respective return periods.

based on the outcome of a crop-cutting exercise undertaken by the Bangladesh Bureau of Statistics at the *upazila* level. If the average yield from 30 randomly selected plots from the *upazila* was less than or equal to 26 maunds per acre, the policy would pay out BDT 300.¹⁰ Each policy could pay out a maximum of one time based on the greatest severity of the three events—if any—that occurred.

Table 3.3 Insurance policy triggers

| Event | Trigger | Description of trigger | Payout |
|--------|---|--|---------|
| First | 14-day dry spell | Maximum number of consecutive dry days when the rainfall recorded at the station is less than or equal to 2 mm in the coverage period is 14 or more days | BDT 600 |
| Second | 12-day dry spell | Maximum number of consecutive dry days when the rainfall recorded at the station is less than or equal to 2 mm in the coverage period is 12 or 13 days | BDT 300 |
| Third | Average yield in the <i>upazila</i> is less than or equal to 26 maunds per acre | Average yield (as estimated by crop cutting experiment conducted at <i>upazila</i> by the Bangladesh Bureau of Statistics) is less than or equal to 26 maunds per acre | BDT 300 |

Source: Authors.

Note: Insurance payouts estimated by actuarial scientists based on data from Bangladesh Bureau of Statistics. BDT = Bangladeshi takas.

The base cost per unit of insurance was BDT 100, roughly 10 percent lower than the actuarially fair price. Although not directly tied to production, each policy was meant to cover revenue from 10 decimals (0.1 acres) of land cultivated under rice. On average, households in the sample cultivate roughly 50 decimals under aman rice during the monsoon season, so each policy unit covered about one-fifth of the rice area cultivated in this season. Each household had the option to purchase multiple units of the insurance based on the amount of land it cultivated during the rainfed agricultural season. However, households could purchase insurance for cultivated land only, so that a household could not purchase insurance coverage for more land than it cultivated, thereby reducing any incentive to view the insurance as a lottery or gamble.

Insurance Marketing

Informational sessions were held in all treatment villages, during which trained product specialists from GUK introduced the insurance product. These training sessions were held about two weeks in advance of the actual sales period. The training sessions typically consisted of 15 to 20 participating households, including both the female (GUK member) and her husband or other male family member responsible for decision making. All households that were GUK members within these villages were invited to attend these sessions and were eligible to buy the insurance as long as they cultivated they own- or rented land during the monsoon season. A large percentage of invited households (more than 96 percent for each focus group meeting) attended these sessions.

Each training session lasted three to four hours and was designed to provide information to help farmers make well-informed decisions about whether or not to purchase insurance. Each session discussed the nature of risk to agricultural production and the strategies that households could use to cope with these risks. The insurance product that was being offered was described and the possibility of basis risk discussed. Various hypothetical cases were considered for the purpose of exposition. The session concluded by setting a date and time for the follow-up informational session and describing how participants could go about purchasing the insurance product, if interested. To simplify the purchasing process, agents distributed insurance demand forms that participants were asked to complete prior to the next appointment.

¹⁰ A *maund* is a unit of mass commonly used in much of South Asia, roughly equivalent to 40 kg.

Since many index insurance programs have suffered from low demand in the past, we were interested in studying the differential effects of alternative incentive mechanisms on insurance demand. To this end, we randomly allocated half of the villages in the treatment group to receive an instantaneous discount (reduction in the purchase price), while the other half received a rebate (a portion of the purchase price refunded at a later date, toward the end of the aman season). We further randomized the level of discount or rebate received at the village level with a skewed distribution such that a higher proportion of sample villages were eligible to receive a higher monetary incentive, in order to ensure a reasonable demand for the insurance. Table 3.4 provides the distribution of villages by the level of discount or rebate. Within the rebate group, the timing of receipt of the rebate was further randomized at the individual level. Half of the farmers in the rebate group received the rebate at the end of the agricultural season and the other half received it during a lean season prior to harvest when farmers' cash flow is most constrained.¹¹

Table 3.4 Distribution of discounts and rebates among treatment villages

| Level of discount/ rebate (percent) | Number of villages in treatment group | | |
|---|---------------------------------------|--------|-------|
| | Discount | Rebate | Total |
| 10 | 1 | 1 | 2 |
| 20 | 1 | 1 | 2 |
| 30 | 1 | 1 | 2 |
| 40 | 1 | 1 | 2 |
| 45 | 1 | 1 | 2 |
| 50 | 1 | 1 | 2 |
| 55 | 1 | 1 | 2 |
| 60 | 2 | 2 | 4 |
| 65 | 3 | 3 | 6 |
| 70 | 4 | 4 | 8 |
| 75 | 5 | 5 | 10 |
| 80 | 3 | 3 | 6 |
| 85 | 1 | 1 | 2 |
| 90 | 6 | 6 | 12 |
| Total | 30 | 30 | 60 |

Source: Authors.

Participants were informed at the end of the training session that they would receive a discount or rebate. The value of the discount (rebate) the village was to receive was randomly selected in the training session. Thus, participants were aware of the effective purchase price for insurance as well as any future refunds they would be entitled to prior to committing to purchase insurance.

In every treatment village, four such information sessions were held to ensure that households were well informed and in the best position to make the decision to purchase the insurance. Apart from GUK membership, there were no restrictions on who could attend a given information session, so those who had previously attended one session could attend subsequent sessions in order to address any questions or to purchase the insurance. Indeed, given the high participation rates throughout the study, it is clear that many GUK members attended all of these information sessions.

¹¹ Individuals were not notified prior to making the decision to purchase insurance whether they would receive the rebate during the lean season or at the end of the season, so it is not possible that this variable could have affected insurance demand.

Weather Realizations and Index Insurance Performance

Based on rainfall measurements at the three *upazila* agricultural extension offices, severe droughts (dry spells exceeding 14 days) occurred in each of the *upazilas* during the aman 2013 season. Figure 3.3 plots the cumulative rainfall in the three *upazilas* during the course of the insurance coverage period. Despite the *upazilas* being in relatively close proximity, Figure 3.3 highlights the extent to which rainfall realizations can vary over space during an insurance coverage period, ranging from 616 mm in Bogra Sadar *upazila* to only 317 mm in Sariakandi *upazila*. In Bogra Sadar *upazila*, there was a 16-day dry spell from September 10 through September 25; in Gabtoli *upazila*, there was a 16-day dry spell from September 13 through September 28; in Sariakandi *upazila*, there was a 14-day dry spell from September 12 through September 25. Because these dry spells met or exceeded the upper threshold specified in the insurance contracts, all policyholders were entitled to a BDT 600 payout per unit of insurance purchased. GUK administrators ensured that all payouts to farmers were distributed within one month of the culmination of the insurance coverage period.

Figure 3.3 Cumulative rainfall during insurance coverage period (July 15–October 14, 2013), by *upazila*

Note: Gray bars indicate the maximum dry spell recorded in each *upazila*.

4. DEMAND FOR INDEX INSURANCE

Empirical Approach

We begin by exploring the determinants of index insurance demand. Here, we focus only on the households from the treatment villages. Our randomization of treatment villages to receive either a discount or a rebate allows us to compare how these two incentives affected households' insurance purchasing decisions, and additional randomization of the level of discount or rebate allows us to assess farmers' sensitivity to these incentives and, ultimately, to the cost of insurance. Because take-up of insurance was very high (89 percent of households in the treatment villages purchased at least one unit of insurance), we focus on how the level and nature of the incentive and other characteristics affected the coverage level (that is, the number of units) that farmers purchased. Among those farmers who purchased insurance, the average coverage amount purchased was nearly 3 units, though there was a nontrivial number of households that purchased 10 or more units (up to a maximum of 25 units). To put this into perspective, on average farmers purchased insurance to cover roughly 83 percent of their total land area under aman cultivation.

We first estimate the following equation to estimate the impact of the discounts and rebates on demand:

$$Y_i = \alpha + \beta L_i + \theta (L_i \times R_i) + \varepsilon_i, \quad (1)$$

where Y_i is the number of insurance units purchased by household i , L_i is the level of the rebate or discount, R_i is a binary variable indicating whether a household received a rebate ($R_i = 1$) or a discount ($R_i = 0$), and ε_i is an idiosyncratic error term.

So long as $\beta > 0$ and $\beta + \theta > 0$ insurance demand will be increasing in both discounts and rebates. Both theory and empirical evidence would largely support both of these predictions, though there has not yet emerged a consensus as to the relative magnitudes of these incentive response slopes. Where the literature is less clear is in regards to prediction of whether $\theta > 0$. In general, the impact of a discount is expected to be larger than the impact of a rebate (that is, $\theta < 0 < \beta$) due to present bias, greater liquidity constraints at the beginning of the season than at the end of the season, and the uncertainty that may surround whether or not the rebate will be paid. Such a finding would be consistent with Epley et al. (2006), who found that people are generally more likely to spend income framed as a gain from a current wealth state (such as a discount on the cost of purchase) than income framed as a return to a prior state (such as a rebate). An important distinction, however, is that in our case, we are not observing the response of receiving a rebate, but rather the present response to the expectation of a future rebate.

Alternatively, a recent study by Serfilippi et al. (2016) demonstrated how insurance demand can actually increase when a specific type of premium rebate is offered (one in which the insurance cost is deducted from the indemnity). This rebate changes the insurance proposition from one in which costs are certain and benefits are uncertain to one in which both costs and benefits of insurance are uncertain. When costs are uncertain, the associated disutility of the insurance cost is discounted by a penalty for uncertainty (under discontinuous preferences; see Andreoni and Sprenger 2010), and such insurance contracts are actually more attractive than more traditional contracts without such rebates. Serfilippi et al. (2016) argued that this is consistent with individuals' having a strong preference for certainty as demonstrated in the Allais paradox and more recently modeled by Andreoni and Sprenger (2010). We may find that the rebate has heterogeneous effects depending on the degree to which individuals are credit constrained, value the present over the future, value certainty, or perceive the benefits of the insurance as uncertain.

To assess whether rebates have heterogeneous effects on insurance demand, we estimate the following equation:

$$Y_i = \alpha + \beta L_i + \theta (L_i \times R_i) + \sum_{j=1}^J \gamma_j x_{ij} + \sum_{k=1}^K \phi_k (z_{ik} \times R_i) + \varepsilon_i, \quad (2)$$

where $x_i = \langle x_{i1}, x_{i2}, \dots, x_{iJ} \rangle$ is a vector of household- and farm-level characteristics and $z_i \subset \mathbf{x}_i = \langle z_{i1}, z_{i2}, \dots, z_{iK} \rangle$ is a subset of household-level characteristics (time preferences, sufficiency of cash savings, sensitivity to basis risk, and risk aversion) that are used to test for heterogeneous rebate effects, and ε_i is an idiosyncratic error term. The parameter vector $\phi = \langle \phi_1, \phi_2, \dots, \phi_K \rangle$ also provides some valuable insight into insurance demand, particularly with respect to dimensions of demand heterogeneity.

Results

The results of estimating equations (1) and (2) by least squares are shown in Table 4.1. Not surprisingly, demand for insurance is price sensitive, with demand increasing with the level of the associated discount or rebate, and robust to various specifications. These results also suggest that demand for insurance would be almost nil without any sort of incentive. In the most parsimonious specification (column [1]), the results suggest that, on average, there would not be any demand for insurance (that is, average demand would not amount to a single full unit per household) unless there was at least a 14 percent discount or a 34 percent rebate on the cost of insurance. This is consistent with the oft-cited narrative that farmers are not willing to purchase any form of crop insurance, even at actuarially fair prices. Even after controlling for household- and farm-level characteristics that could plausibly affect insurance demand (column [2]), we find that, on average, there would not be any demand for insurance without at least a 27 percent discount or a 66 percent rebate.

These results suggest that farmers prefer discounts to rebates. Overall, we observe that farmers being offered a discount on the cost of insurance (averaging roughly 67 percent off the base cost of the insurance policy) purchased roughly 3.7 units of insurance, whereas farmers being offered a rebate (also averaging roughly 67 percent of list price) purchased only about 1.2 units of insurance. For a given incentive level, receiving a rebate instead of a discount results in roughly 59 percent fewer units purchased. The timing of the implicit cost reduction is clearly important in farmers' insurance purchasing decisions.

We also examine whether individuals who are more patient reduce their demand less when faced with a rebate instead of a discount. Our estimates of the implicit discount rate among the farmers in our sample, from survey responses, suggest a substantial discounting of future receipts (on average, a roughly 271 percent annual discount rate). But our econometric results, reported here, do not support the notion that farmers' preference towards the present influences their demand response to a rebate relative to a discount. Indeed, if there is any evidence of the influence of time preferences on insurance demand, it suggests that farmers with a higher discount rate would demand more insurance if they were given a rebate rather than a discount, though we note that this interaction term (hyperbolic discount rate \times rebate dummy) is not significantly different from 0 at conventional levels. We also find no evidence that those who are more cash constrained are affected differently by a rebate.

Next, we assess whether rebates may work to counter the uncertainty of future payouts. We examine the effect of sensitivity to basis risk on insurance demand.¹² Although the point estimate on the main effect is negative (though insignificant), suggesting that farmers sensitive to basis risk might purchase fewer units than those not especially sensitive to basis risk, the interaction effect between basis risk sensitivity and receiving a rebate is positive, suggesting that receiving a rebate increases insurance demand among those sensitive to basis risk, relative to receiving a discount (though again, we note that the p -value on this interaction term is only 0.41).

¹² Basis risk sensitivity is determined based on responses to two different questions. First, suppose you bought insurance each year for five years. You paid the premium each year and the rains were fine five years in a row, so you did not receive a payout. Would you still be interested in purchasing insurance next year? Second, suppose you purchased insurance this year. The rains failed on your field but were sufficient at the weather station where the index is measured, so you did not receive a payout. Would you still be interested in purchasing insurance next year? If the response to both questions was no, the farmer was considered sensitive to basis risk and was coded as 1, or 0 otherwise. An alternative approach to evaluating the effect of basis risk on insurance take-up might be to capture the distance between farmers' fields and the location at which the index measurement are recorded. This would be similar to the approach illustrated by Mobarak and Rosenzweig (2012), who showed that insurance demand decreases in this distance. Our view, however, is that even if farmers were aware of the objective degree of basis risk that they were exposed to, their subjective sensitivity to this risk is what would be correlated with their insurance purchasing decisions.

Table 4.1 Estimates of insurance demand

| Variable | (1) | (2) | (3) | (4) | (5) | (6) | (7) |

Note: * Significant at 10% level; ** significant at 5% level; *** significant at 1% level. Standard errors adjusted for clustering at the village level in parentheses. Household/farm controls include household head age, gender, and highest education level; household size; asset holdings (index, constructed by principal components analysis); the length of time the household has been a member of GUK; total land holdings; a binary indicator for whether the household has a savings account at a formal financial institution; a binary indicator for whether the household is a member of an informal savings group; the sufficiency of cash savings; and a binary indicator as to whether the household believes most financial institutions can be trusted.

A similar effect emerges when we look at risk aversion.¹³ We see that more risk-averse farmers purchase fewer units than those less sensitive to risk, an effect that is statistically different from 0 at the 5 percent level. At first glance, this finding may be surprising, inasmuch as traditional expected utility theory would predict that high degrees of risk aversion should increase insurance uptake. This finding, however, is somewhat of an empirical regularity, having been previously found in Giné et al. (2008); Giné and Yang (2009); and Cole et al. (2013). In many cases, the insurance product itself is risky, particularly for index insurance products that carry nontrivial basis risk. We test for the presence of an inverse U-shaped relationship between insurance demand and risk aversion as predicted by Clarke (2016), but we do not find any evidence of such nonmonotonicity with respect to risk aversion (not shown in Table 4.1), perhaps because our sample of farmers exhibits quite high levels of risk aversion, causing the average coefficient on risk aversion to be negative, or because of high expected contract nonperformance. What we do find, however, is that when we interact the partial risk aversion coefficient with the rebate dummy, demand is higher for those receiving a rebate relative to those receiving a discount (for a given level of risk aversion and a given incentive amount), and this effect is also statistically different from 0. For those that are risk averse or especially sensitive to basis risk, the promise of a rebate may provide assurances that they will have some financial recompense in the future, even if they suffer significant crop losses and are not indemnified by the index insurance product.

¹³ Risk aversion was measured using a survey-based instrument similar to the one used by Binswanger (1980). In particular, respondents were asked the following: Imagine you are going to flip a coin and you win the amount under the green area if it lands on heads or the amount in the white area if it lands on tails. The amount you win depends on the bet you choose. Which bet would you choose? Respondents were then shown a visual aid with the following payoff pairs (green/white): (a) BDT 50/50; (b) BDT 40/100; (c) BDT 30/130; (d) BDT 20/160; (e) BDT 10/200; (f) BDT 0/220. Based on the response, we assigned to the participant a coefficient of partial risk aversion consistent with his or her choice.

5. EFFECTS OF INSURANCE ON AGRICULTURAL INTENSIFICATION

Empirical Approach

We now move to estimating the effects of the index insurance product on agricultural intensification. In particular, we estimate the effects of insurance on investments in modern agricultural inputs (specifically, irrigation, pesticides, fertilizer, hired labor, and purchased seeds) and on agricultural production (specifically, total land cultivated under rice, total rice harvested, and rice yields) in the primarily rainfed aman season. Section 2 highlighted that insurance increases risk-averse producers' demand for risk-increasing inputs and reduces their demand for risk-reducing inputs (Quiggin 1992). Thus we would expect to see farmers increasing their use of risk-increasing inputs, such as fertilizer and improved seeds, or inputs that increase the scale at which they farm, such as land cultivated and labor hired. We would also expect spending on risk-reducing inputs such as pesticides to fall.

The expected impact of insurance on irrigation expenditure is more nuanced. Irrigation is a risk-reducing technology in that it provides an alternative method for managing drought risk: farmers can simply “turn on the tap” during prolonged dry spells or when monsoon rainfall is otherwise deficient. At face value, therefore, we would expect spending on irrigation to fall, and had we offered a contract that indemnified farmers on the basis of their yields alone, this might have been the case. However, these hypotheses are predicated on decision makers' contemplating *production* risk and receiving *production* insurance, when in fact what may be driving decisions is *profit* risk and in this case the insurance provided addresses some cost-of-production risk. Farmers in Bogra typically purchase groundwater from a tube well pump owner and, when faced with successive dry days, often choose to wait one or two more days to see whether their crops will survive without their incurring the cost of supplemental irrigation. By making payouts for successive dry days as well as lowered realized yields, the insurance contract guaranteed farmers that they would receive a payout to cover the increased cost they faced in irrigating their crop during these dry spells. Thus, for the insurance contract provided, we would expect spending on irrigation to increase.

Although theory predicts that changes in input use induced by the provision of insurance will increase a producer's overall exposure to high production outcomes and increase average production, it does not guarantee that in any one season production outcomes will be higher. In fact, in bad states of the world, production outcomes could still be lower as a result of the use of strongly risk-increasing inputs.

As previously described, the insurance was offered immediately prior to the 2013 aman season, and the *upazila* agricultural extension offices recorded dry spells lasting at least 14 days in each *upazila*, thereby triggering the insurance payout of BDT 600 per unit of insurance purchased.¹⁴ These payments were made by early December 2013—around the time when farmers were planting their boro crops. The timing of the payouts provided liquidity right around the time that farm households were making investments for the 2013/2014 boro season. This suggests some potential that purchasing insurance could directly affect the subsequent agricultural season despite its being outside of the specified insurance coverage period. We therefore also examine the impact of insurance on modern agricultural input use and agricultural production in the irrigated boro season.

The ensuing analysis presents only the intention-to-treat (ITT) effects (that is, the effect of being randomly allocated to the group being offered insurance, regardless of whether the household actually purchased the insurance) rather than the average treatment effect on treated households (that is, the effect of purchasing insurance if randomly assigned to the group being offered insurance).¹⁵ Given the high

¹⁴ Although the insurance itself was not tied to actual on-farm production, each unit of insurance was meant to provide coverage for an area of up to 10 decimals (0.1 acres).

¹⁵ Because the actual receipt of treatment is endogenous (due to households making the decision to purchase insurance), the ITT effect is a biased estimator for the average treatment effect among households that actually purchase insurance. Assuming the correlation between purchasing insurance and agricultural intensification is positive, ITT effects will be downwardly biased, with the magnitude of the bias a function of the proportion of those randomly assigned to be offered insurance who made the decision to actually purchase coverage.

take-up rates in the present study, reliance on the ITT estimates does not result in significantly attenuated estimates of average treatment effects. Furthermore, such estimates provide broad insight into the potential impact of an insurance program that is introduced at scale.

In the vast majority of applications, treatment effects on economic outcomes are estimated using a difference-in-differences estimator that is essentially a generalization of an analysis of variance (ANOVA) of change. It has been shown that, when autocorrelation in the outcomes of interest is low, there are significant gains in statistical power from employing alternative empirical approaches (for example, see Frison and Pocock 1992; McKenzie 2012; Van Breukelen 2006). One particular estimator that increases statistical power simply by controlling for baseline values of the outcome variable is the analysis of covariance (ANCOVA) estimator (McKenzie 2012):

$$\delta_{ANCOVA} = (\bar{Y}_1^T - \bar{Y}_1^C) - \hat{\beta} (\bar{Y}_0^T - \bar{Y}_0^C), \quad (3)$$

where \bar{Y}_j^i is the mean outcome variable in the treatment ($i = T$) and comparison ($i = C$) groups at the study baseline ($j = 0$) and endline ($j = 1$); $\hat{\beta}$ captures the effect of differences in the preintervention levels of the group means for the outcome variable; and δ_{ANCOVA} is the ANCOVA estimate of the effect of random assignment to the treatment group.¹⁶ As Van Breukelen (2006) has noted, $\hat{\beta}$ is a function of both the within-group variance and correlations in the pre- and postintervention values of the outcomes. This equation can be operationalized using least squares by estimating the regression equation

$$y_{i1} = \alpha + \beta y_{i0} + \delta T_i + \mathbf{x}_{i0}' \gamma + \varepsilon_i, \quad (4)$$

where y_{i1} and y_{i0} are the endline and baseline levels of the outcome of interest, respectively; T_i is the binary treatment indicator; \mathbf{x}_{i0} is a vector of covariates to control for baseline imbalance; and ε_i is an idiosyncratic error term. The α , β , δ , and γ terms are parameters to be estimated. Specifically, δ is an estimate of the impact of the insurance treatment on the outcome variable. Given that exposure to the information and insurance treatments will be similar among GUK members in a particular village, we relax the assumption that error terms are independently and identically distributed, but rather allow for error terms to be independent across villages but correlated within villages. We estimate equation (4) by least squares to arrive at estimates of the ITT effects of our insurance product on the aforementioned indicators of agricultural intensification.

Results

Estimated impacts for the 2013 aman season are reported in Table 5.1, and estimated impacts for the 2013/2014 boro season are reported in Table 5.2.¹⁷ Focusing first on the risk-mitigation effects during the aman season (Table 5.2), we find that farmers participating in the treatment spent roughly BDT 1,400 more on agricultural inputs than did farmers in the comparison group, representing a nearly 16 percent increase over comparison farmers. This increase in input expenditures is not, however, distributed evenly over all inputs. We find that being offered index insurance resulted in a BDT 250 increase in irrigation expenditures (a nearly 30 percent increase over comparison farmers), a roughly BDT 600 increase in

¹⁶ Note that this is different from the classical difference-in-differences estimator, which can be written as $\delta_{DD} = (\bar{Y}_1^T - \bar{Y}_1^C) - (\bar{Y}_0^T - \bar{Y}_0^C)$.

¹⁷ In the regressions summarized in Tables 5.1 and 5.2, we treat total agricultural expenditures and expenditures on irrigation, pesticides, fertilizer, labor, and seeds as independent outcomes, with each independent outcome associated with a unique hypothesis test. In reality, since agricultural inputs are often complementary, our estimation strategy could permit free correlation in error terms across expenditure impact regressions. This could be accomplished by estimating the expenditure impact regressions simultaneously as a “seemingly unrelated regression.” Though not reported here, we have indeed estimated such relationships, and due to the positive correlations between error terms among these different expenditure categories, we have found both larger and more statistically significant impacts in both aman and boro seasons. The estimated effects reported here should, therefore, be treated as conservative estimates of the impact of insurance on input expenditures.

fertilizer expenditures (an almost 20 percent increase over comparison farmers), and a roughly BDT 70 increase in pesticide expenditures (an almost 20 percent increase over comparison farmers). The increased use of fertilizers is consistent with theoretical predictions that risk management induces investments in higher-risk, higher-return activities, with unambiguous predictions regarding strongly risk-increasing inputs like fertilizer. Fertilizer has the potential to substantially increase yields, but because it is expensive and carries the potential for significant crop losses under adverse conditions, farmers are often reluctant to invest in applying chemical fertilizers in an environment of unmanaged risk. This finding that insurance increases fertilizer application (or, more accurately, expenditures on fertilizers) is consistent with other research, both theoretical and empirical (for example, Quiggin 1992; Alderman and Haque 2007; Karlan et al. 2014).

The increase in irrigation costs is also consistent with theory, given that the insurance contract offered protection against this cost of production in the presence of many successive dry days, as was the case in the 2013 aman season. This result highlights how insurance provided to mitigate the costs associated with managing shocks can also encourage households to take appropriate actions to reduce the impact of weather shocks on income.

The estimated effect of insurance on increasing pesticide expenditures is positive as well, though only marginally significant (p -value of 0.11). This effect could be considered surprising, because theory would predict expenditures on risk-reducing inputs such as pesticides to decline with insurance take-up. However, given that this was an index insurance product, this result is perhaps not as counterintuitive as it appears at first glance. Although the yield risk posed by pests was covered in the average area yield index, a farmer receive a payout only if average yields were significantly impacted (whether by pests or otherwise), not if just his or her plot was affected. Furthermore, the area yield measurements were considered only if neither of the dry-day thresholds was triggered. Increasing expenditures on pesticides helps to reduce some of the risks and associated costs of insurance contract nonperformance by minimizing farmers' exposure to risks not covered by the insurance contract. It could also be the case that attendance at the training session and the purchase of insurance made the issue of managing risk more salient to farmers, thereby encouraging them to apply pesticides when needed. We note, however, that any increase in pesticide expenditures is relative to an extremely low base. At baseline, pesticide expenditures accounted for only 4.4 percent of total aman season agricultural expenditures.

Table 5.2 reports the least squares ITT impacts on agricultural intensification during the boro season. As with impacts during aman season, we find that being exposed to the index insurance product led farmers to spend more on agricultural inputs than those who were never exposed to the insurance product—in the case of boro rice, nearly BDT 910 (6.9 percent) more than farmers in the comparison group (though this estimated effect on total agricultural expenditures is not statistically significant at conventional levels, with a p -value of 0.17). Again, as before, the increased expenditures are not spread uniformly over the different inputs. In fact, the only statistically significant effect of insurance exposure on input use is an increase in seed expenditures.¹⁸ Exposure to the insurance product increase seed expenditures by nearly BDT 119, representing a roughly 28 percent increase in seed expenditures over those of farmers in the comparison group. Because the insurance product was marketed prior to and covered the aman season, we cannot attribute these effects to risk management effects (because boro-season risks remained uninsured). However, because the insurance payments were made following the aman harvest and just prior to the initiation of the boro season, these income effects likely arose due to insured farmers' realizing increased liquidity. Because we do not have data on how insured farmers might

¹⁸ In addition to this effect on seed expenditures, there is a marginally significant positive effect on fertilizer expenditures (p -value of 0.12).

Because we do not have data on how insured farmers might have behaved with respect to their boro input expenditures in the absence of an insurance payout (which, consequently, means in the absence of a measured drought or crop loss during the aman season), we cannot say for certain that this effect would only hold only after receipt of an insurance payout. If indeed the increased seed expenditures during boro arose due to an income effect, then perhaps there would be no reason to expect this sort of response in the absence of an insurance payout, especially because, as Table 5.1 shows, there was no discernible effect on aman production.¹⁹

The increased expenditures on seeds during the boro season are important for several reasons. First, while grain from most rice varieties can be stored and used for seeds in subsequent generations, such seed saving necessarily limits farmers' access to the technological improvements (for example, higher yields, biotic and abiotic stress tolerance, and so on) embodied in newer varieties (Spielman et al. 2013). Second, saved seeds tend to suffer from physical and genetic deterioration over time. For example, saved seeds may have lower germination rates than do new seeds, so farmers may need to sow at higher seeding rates to achieve levels of crop emergence comparable to those of new seeds. Third, the increased seed expenditures may signal farmers' transition from inbred rice varieties to rice hybrids, which are almost exclusively cultivated during the dry winter season (in which boro rice is cultivated) in Bangladesh. Although hybrids are considerably more expensive than inbred varieties (even high-yielding varieties) and must be purchased anew every season, they also confer significantly higher yields and have greater genetic uniformity and vigor, which enables farmers to sow at much lower seeding rates (Spielman et al. 2016). Additionally, because hybrids are almost exclusively developed by the private sector, there is greater potential for technological innovations in hybrids than in varieties developed by the public sector. Though we do not know for certain that the increased seed expenditures point to the use of hybrids, their relative magnitude makes such a scenario plausible.

We find a positive and statistically significant effect of insurance on both the area cultivated under boro and the subsequent rice harvest, though based on our analyses we are unable to detect an increase in productivity. We are somewhat cautious about being too enthusiastic about the measured effects on cultivated area. Previous research (for example, Abate et al. 2015) has found that farmers are remarkably skilled at estimating their total production yet tend to systematically measure plot sizes with error, such as rounding off their area estimation and making errors in converting from local units to a standard areal unit such as an acre. Farms in Bangladesh typically consist of several very small and fragmented plots, so it is easy to see how rounding errors can be compounded as the number of plots increases. Since yield data are constructed based on self-reported production and area data, it is plausible that the lack of a significant effect on yields is due to errors in measuring cultivated area. These errors in measuring plot sizes would then, by definition, translate into errors in yield measurements. Specifically, if area measurements are systematically biased upward, then for a given production level, the computed yield would be downwardly biased. Measurements of total production are less prone to such systematic measurement errors and may therefore serve as more reliable estimates of the impacts on production of the increased seed expenditures. Given the significant effect that the insurance had on increasing seed purchases, and the presumption that the driving force behind such purchases being a quest for higher yields, it seems plausible that the increase in total production is attributable to increases along the intensive—rather than extensive—margin.

¹⁹ It is possible that risk management during the aman season might also produce an income effect that results in increased seed expenditures during the boro season, regardless of whether an insurance payout was received. Admittedly we do not have an adequate counterfactual at our disposal with which to test this hypothesis, so it remains largely conjectural. Suppose there was *not* a drought during the aman season. Because we observe higher expenditures on modern inputs among insured farmers (vis-à-vis farmers in the comparison group) as a result of risk management (independent of the resultant state of nature), and because we would expect strictly positive marginal productivities for all inputs during aman production under such conditions, total aman output for insured farmers should exceed that of uninsured farmers. This, in turn, could produce an income effect similar to that of the insurance payment and induce increased expenditures on fertilizers during the boro season. The relative magnitudes are impossible to quantify in the absence of a proper counterfactual, but it seems at least plausible that the income effects and increased input expenditures during the boro season could at least indirectly result from the risk management effects that arise during the aman season.

6. CONCLUDING REMARKS

This paper presents early results from a weather-based index insurance program in rural Bangladesh. The pilot provided treated farmers with easily verifiable and transparent insurance coverage against specified dry spells during the aman season, backed by coverage assessed on an area yield basis. The empirical analysis focuses on the determinants of insurance demand as well as the subsequent effects of insurance on agricultural intensification and rice production. The results provide valuable insight into the potential viability of insurance markets in rural Bangladesh, as well as the potential benefits that such an insurance product might provide, in terms of both risk management and increased income.

In our analysis of insurance demand, results are consistent with much of the empirical literature demonstrating that demand for insurance is price sensitive. In the absence of financial incentives such as discounts or rebates, our results suggest there would be essentially no demand for the insurance product, even at market prices below actuarially fair levels. The nature of the incentive also plays a role in stimulating demand. Up-front discounts on the cost of insurance are much more successful at stimulating insurance take-up than are rebates, which necessarily involve a delay in the receipt of the monetary inducement. This effect impacts not only whether individuals decide to purchase insurance but also the coverage level that they purchase. On average, individuals receiving a discount purchased roughly 3.7 units of insurance, but those offered a rebate purchased only 1.2 units of insurance. Interestingly, demand among some farmers in the sample (particularly very risk-averse farmers and those especially sensitive to the presence of basis risk) responded more favorably to the rebate, perhaps because the rebate would help to offset the costs of contract nonperformance (that is, basis risk), by providing the assurance of some financial inflow in the future even if the insurance contract never paid out.

In our analysis of the impacts of insurance on agricultural intensification and rice production, we find evidence of both *ex ante* and *ex post* impacts. The *ex ante* impacts, which we consider to be pure risk management effects, translate into significantly higher expenditures on several agricultural inputs during the aman rice-growing season. Specifically, we find that insurance led to significantly higher expenditures on irrigation and fertilizer, with a marginally higher impact on pesticide expenditures. At first glance, the effects on irrigation and pesticide expenditures are contrary to theoretical predictions, given that both inputs reduce production risk. However, the insurance contract offered helped to cover costs when farmers used irrigation to combat successive dry days, and thus the contract increased expenditure on this risk-mitigating input. The results highlight that appropriately designed insurance contracts can encourage beneficial risk-mitigation behavior. Additionally, the effects on pesticide expenditures—which, notably, are relatively small as a share of overall agricultural expenditures—may arise due to the nature of index insurance. Farmers increase expenditures on pesticides and thus reduce the risks and associated costs of basis risk.

During the boro season, insurance resulted in increased expenditures on seeds and, consequently, higher rice production. Because the insurance contract was designed to manage only aman-season risks, this impact cannot be considered a risk management effect. Rather, due to the timing of the insurance payouts (following the aman harvest and prior to boro land preparation), this *ex post* effect reflects the increased income or liquidity that insured households reaped, in this case as a result of the insurance payout. Given insufficient exogenous variation in insurance payout receipts (because all insured farmers received a payout), we are unable to say with any degree of certainty that this effect would be present only following an insurance payout (which, in turn, occurs only in the event of a drought measured through rainfall at the agricultural extension office or reduced yields measured through crop-cutting exercises). This causal pathway seems plausible, though we also suggest that such an income effect could occur even in the absence of an insurance payout, for example due to increased farm profits from aman production (because the *ex ante* effects of insurance increased agricultural intensification during the aman season). Parsing out this effect remains a task for future research.

The results highlighted here come from a single study spanning two agricultural seasons. Furthermore, these results are compelling largely due to the very high take-up rates, which were induced by very high incentives on favorably-priced index insurance. It remains to be seen whether such an index insurance program is sustainable, whether positive experiences with insurance programs can stimulate demand even without incentives, or ultimately, whether the ex ante and ex post impacts of insurance would be realized without the sizable incentives. The large number of related studies that are ongoing in other countries should provide more insight into these unanswered questions.

RECENT IFPRI DISCUSSION PAPERS

For earlier discussion papers, please go to www.ifpri.org/publications/discussion_papers.
All discussion papers can be downloaded free of charge.

1629. *Nutrition incentives in dairy contract farming in northern Senegal*. Tanguy Bernard, Melissa Hidrobo, Agnes Le Port, and Rahul Rawat, 2017.
1628. *Chinese investment in Ghana's manufacturing sector*. Xiaoyang Tang, 2017.
1627. *Participation, learning, and equity in education: Can we have it all?* Clara Delavallade, Alan Griffith, Gaurav Shukla, and Rebecca Thornton, 2017.
1626. *Limitations of contract farming as a pro-poor strategy: The Case of maize outgrower schemes in upper west Ghana*. Catherine Ragasa, Isabel Lambrecht, and Doreen S. Kufoalor, 2017.
1625. *Cooperation in polygynous households*. Abigail Barr, Marleen Dekker, Wendy Janssens, Bereket Kebede, and Berber Kramer, 2017.
1624. *Farmers' quality assessment of their crops and its impact on commercialization behavior: A field experiment in Ethiopia*. Gashaw Tadesse Abate and Tanguy Bernard, 2017.
1623. *Changing gender roles in agriculture?: Evidence from 20 years of data in Ghana*. Isabel Lambrecht, Monica Schuster, Sarah Asare, and Laura Pelleriaux, 2017.
1622. *Improving the targeting of fertilizer subsidy programs in Africa south of the Sahara: Perspectives from the Ghanaian experience*. Nazaïre Houssou, Collins Asante-Addo, and Kwaw S. Andam, 2017.
1621. *El agro Argentino: Un sistema productivo y organizacional eficiente*. Valeria Piñeiro, Miguel Robles, and Pablo Elverdin, 2017.
1620. *Local corruption and support for fuel subsidy reform: Evidence from Indonesia*. Jordan Kyle, 2017.
1619. *Smog in our brains: Gender differences in the impact of exposure to air pollution on cognitive performance in China*. Xi Chen, Xiaobo Zhang, and Xin Zhang, 2017.
1618. *Existing data to measure African trade*. Cristina Mitaritonna and Fousseïni Traoré, 2017.
1617. *Misreporting month of birth: Implications for nutrition research*. Anna Folke Larsen, Derek Headey, and William A. Masters, 2017.
1616. *He says, she says: Exploring patterns of spousal agreement in Bangladesh*. Kate Ambler, Cheryl Doss, Caitlin Kieran, and Simone Passarelli, 2017.
1615. *Forced gifts: The burden of being a friend*. Erwin Bulte, Ruixin Wang, and Xiaobo Zhang, 2017.
1614. *Institutional versus noninstitutional credit to agricultural households in India: Evidence on impact from a national farmers' survey*. Anjani Kumar, Ashok K. Mishra, Sunil Saroj, and P. K. Joshi, 2017.
1613. *Cost-effectiveness of community-based gendered advisory services to farmers: Analysis in Mozambique and Tanzania*. Tewodaj Mogues, Valerie Mueller, and Florence Kondylis, 2017.
1612. *The European Union–West Africa Economic Partnership Agreement: Small Impact and new questions*. Antoine Bouët, David Laborde, and Fousseïni Traoré, 2017.
1611. *The returns to empowerment in diversified rural households: Evidence from Niger*. Fleur Wouterse, 2017.
1610. *Prospects for the Myanmar rubber sector: An Analysis of the viability of smallholder production in Mon State*. Joanna van Asselt, Kyan Htoo, and Paul A. Dorosh, 2017.
1609. *How do agricultural development projects aim to empower women?: Insights from an analysis of project strategies*. Nancy Johnson, Mysbah Balagamwala, Crossley Pinkstaff, Sophie Theis, Ruth Meinzen-Dick, and Agnes Quisumbing, 2017.
1608. *Stimulating agricultural technology adoption: Lessons from fertilizer use among Ugandan potato farmers*. Lydia Naziziwa-Nviiri, Bjorn Van Campenhout, and David Amwonya, 2017.
1607. *Strengthening and harmonizing food policy systems to achieve food security: A case study and lessons from Ghana*. Suresh Chandra Babu and Sylvia Blom, 2017.
